SUMMARY This prospective study investigated the difference in clinical efficiency between Damon[™] 3 self-ligating brackets (SLB) compared with Mini Diamond conventional ligating brackets (CLBs) during tooth alignment in straightwire fixed appliance therapy.

Twenty-nine patients (10 males and 19 females), aged between 14 and 30 years, were randomly divided into two groups: 14 patients received the SLB and 15 received the CLB. Upper arch impressions were taken for pre-treatment records (T_0). A transpalatal arch was soldered to both maxillary first molar bands prior to extraction of the maxillary first premolars, followed by straightwire fixed appliances (0.022 × 0.028 inch). A 0.014 inch nickel titanium (NiTi) wire was used as the levelling and aligning archwire. Four monthly reviews were undertaken and impressions of the upper arch were taken at each appointment (T_1 , T_2 , T_3 , and T_4). Displacements of the teeth were determined using Little's irregularity index (LII). Data were analysed using the Mann–Whitney *U*-test.

In the aligning stage, the CLB group showed significantly faster alignment of the teeth compared with the SLB group at the T_1-T_2 interval (P < 0.05). However, there were no differences at T_2-T_3 , and T_3-T_4 for either group (P > 0.05). The CLB group showed 98 per cent crowding alleviation compared with 67 per cent for the SLB after 4 months of alignment and levelling. Mini Diamond brackets aligned the teeth faster than DamonTM 3 but only during the first month. There was no difference in efficacy between the two groups in the later 3 weeks. Alleviation of crowding was faster with CLB than with SLB.

Introduction

The efficiency of treatment mechanics is necessary to ensure optimal treatment results in less clinical time and with a shorter treatment duration. Sliding mechanics in the modern straightwire fixed appliance system have considerably reduced the need for wire bending that was dominant in the standard edgewise technique. However, sliding movements along the archwire still imply friction between the archwire, bracket, and ligature surfaces, taking up part of the applied force and leaving an uncontrolled amount to act on the teeth. It is estimated that 50 per cent of applied orthodontic force is used purely to overcome the friction in the system (Proffit, 2000). Self-ligating brackets (SLB) were developed on the premise that elimination of ligature ties creates a friction-free environment, allows for better sliding mechanics, and may therefore reduce treatment time (Eberting et al., 2001). SLB were first described by Stolzenberg (1935) with his Russell Lock appliance and since then various types of SLB have been fabricated (Harradine, 2008). It is claimed that SLB fulfil the ideal properties of orthodontic ligation by providing fuller archwire engagement with low frictional force between the bracket and archwire. Furthermore, it requires

less chair side assistance and allows faster archwire insertion and removal. In term of treatment time, it was found that there was a mean reduction of 4 months in treatment and four visits during active treatment (Harradine, 2001).

The theory behind the faster treatment time may be related to the low friction that is proposed by the manufacture. Numerous authors, with different study designs and various types of materials, archwire, and bracket slot dimensions, have shown that SLB demonstrate very low friction (Harradine, 2008). Kapur et al. (1998) found significantly lower friction with both stainless steel and nickel titanium (NiTi) wires with SLB compared with conventional brackets. An in vivo study, Lotfus et al. (1999) found that with a simulated periodontal ligament, friction with the Damon SLB was not significantly less than with conventional brackets. However, Thorstenson and Kusy (2002) found that the angulation beyond the angle at which the archwire first contacts the diagonally opposite corners of the bracket slot caused a similar rise in the resistance to sliding of both SLB and conventional ligating brackets (CLB).

It has also been claimed that SLB permits anchorage conservation (Harradine, 2008). This is due to the fact that

lower forces are used for moving the teeth and thus reciprocal forces are correspondingly smaller. Lower forces per unit area lead to more anchorage preservation. The SLB system was found to align teeth at a faster rate than CLB due to the capacity of the wire to slide through the brackets of rotated teeth (Harradine, 2008). Free movement of the archwire significantly facilitates alignment of the rotated tooth and its adjacent teeth. This is because a fully secure bracket engagement permits full embrasure of the displaced teeth and therefore, full control of tooth movement can be achieved.

Some SLB is functionally narrower than conventional brackets. This leads to a wider interbracket span and thus, a longer segment of wire connects the brackets. When the force exerted is proportional to the third power of the length, the deflection of the archwire will be reduced. Hence, lower forces and a longer range of action with any given archwire during the alignment phase (Harradine, 2008). SLB require less time during archwire changes by eliminating the use of any type of ligation. This results in faster archwire ligation and archwire removal, as well as lessening the need for chair side assistance. Voudouris (1997) reported a 4-fold reduction in archwire time change with SLB. In other words, clinical time used to ligate and remove archwires can be 80 per cent shorter.

Several published prospective clinical trials comparing SLB and CLB have shown differences in the effectiveness of SLB systems but no difference in perceived discomfort experienced by the patients (Scott *et al.*, 2008). Comparison between Smart-Clip SLB and CLB in the reduction of crowding over the first 20 weeks of treatment showed no difference between the two bracket types (Miles, 2005). A similar study by Miles *et al.* (2006) that compared Damon 2 and conventional brackets found no difference in the clinical ability to align the teeth. The purpose of this study was to compare the efficacy of DamonTM 3 SLB with Mini Diamond CLB in alignment of the upper labial segment teeth during fixed appliance therapy.

Subjects and methods

The reference population for this prospective study comprised patients awaiting treatment at either the Faculty of Dentistry, Universiti Kebangsaan Malaysia (UKM) or Pusat Pergigian AT, Kementah, Kuala Lumpur. Twentynine patients (10 males and 19 females), between 14 and 30 years of age (mean 20.7 years) who met the inclusion criteria, were invited to participate and were randomly allocated to be treated using either SLB or CLB. The nature of the study was explained to all patients and/or their parents and consent forms were obtained. Ethical approval was given by the UKM, Faculty of Dentistry Research and Ethics Committee.

Inclusion criteria

- 1. Healthy systemic condition/no systemic illness, as reported by patients.
- 2. No use of any form of anti-inflammatory drugs preceding the beginning of study.
- 3. Good oral hygiene and periodontal health with periodontal pockets of less than or equal to 4 mm, full-mouth plaque score less than or equal to 20 per cent, and full-mouth bleeding score less than or equal to 20 per cent (within 15 seconds after pocket depth probing).
- 4. Cooperative and motivated.
- 5. In the permanent dentition with all teeth present at least to the first molars.
- 6. Class I or Class II division 1 incisor relationship with an overjet less than or equal to 6.0 mm (an upper tooth which was in crossbite was accepted provided the orthodontic bracket could be bonded to the tooth and no additional space opening mechanics were needed to align the tooth).
- 7. Extraction of at least both upper first premolars to relieve moderate to severe crowding and/or to reduce the overjet.
- 8. Patients who needed at least upper fixed appliance treatment to retract the maxillary canines.
- 9. No radiographic bone loss was observed on the dental pantomographic image.

Exclusion criteria

- 1. Previous upper removable orthodontic treatment.
- 2. Patients who required surgery to correct skeletal discrepancies.
- 3. Patients with hyperdontia, hypodontia, or syndromic diseases (e.g. cleft lip and palate).
- 4. Uncooperative patients.

All patients underwent a routine orthodontic assessment and were treated by one clinician (HI) under supervision of the principal investigator (RMAW). Prior to the start of treatment, full-mouth scaling and prophylaxis were undertaken and the subjects were instructed correct oral hygiene practice. A transpalatal arch was constructed with suitable molar bands and cemented to the maxillary first molars. Upper alginate impressions were taken as the baseline impression (T₀) just before bonding of either of the bracket systems.

Either Damon[™] 3 or Mini Diamond brackets (Ormco Corporation, Orange, California, USA; 0.025 × 0.028 inches) were bonded on the buccal surfaces of all teeth in both arches with Transbond[™] XT (3M Unitek, Monrovia, California, USA) composite resin according to the manufacturers' recommendation. A 0.014 inch dimension circular cross-sectional NiTi archwire (TruFlex[™]; OrthoTechnology, Inc., Tampa, Florida, USA) was used as the initial aligning archwire and was chinched back (Figure 1). A laceback stainless steel wire (0.010 inch)

Figure 1 A patient treated with (a) Mini Diamond conventional ligating brackets and (b) DamonTM 3 self-ligating brackets during the initial aligning and levelling phase.

was tied lightly from the canine to the molar tooth in every quadrant to prevent deflection of the NiTi archwire during mastication. The patients were recalled at monthly interval for 4 months and an upper impression was taken at each visit (T_1 , T_2 , T_3 , and T_4). The same 0.014 inch round NiTi archwire was used to align the teeth throughout this period, unless there was a need for a replacement, but the wire diameter was kept the same. The overbite, overjet, and molar relationship of each patient and their oral hygiene practice were closely monitored throughout these review appointments. The progress of the study is shown in Figure 2.

Outcome measurements

Little's irregularity index (LII; Little, 1975) was used to assess the overall changes in alignment (Figure 3). All measurements were made on the study models taken at T_0 and during alignment and levelling (T_1 , T_2 , T_3 , and T_4). These measurements were carried out using electronic digital callipers [Series 600—Manual, Absolute Digimatic; Auto Motor Zubehor, Hannover, Germany) with an

Figure 2 Study flow chart.

Figure 3 Measurement of Little's irregularity index.

accuracy of 0.01 ± 0.02 mm. Assessment of the effect of the brackets on tooth movement was determined by subtracting the current reading from the previous reading. Calibration was performed using a set of 14 study models from the Orthodontic Department archive with measurements obtained by RMAW as gold standard.

Statistical analysis

The Statistical Package for Social Sciences (SPSS Inc., Chicago, Illinois, USA) version 15.0 was used to analyse the data, using the Mann–Whitney *U*-test for the LII score

at all stages of alignment due to non-parametric distribution of the data. Z statistics and P values were used to test the significance of the results. P < 0.05 indicated statistical significance.

Results

Patient allocation with gender distribution, types of malocclusion, mean age, and mean pre-treatment LLI are shown in Table 1. A total of 29 patients were recruited into the study, 15 in the CLB, and 14 in the SLB groups. Intra- and inter-examiner reproducibility and reliability assessments showed good agreement, with intraclass correlation coefficient values of 0.996 and 0.995. Descriptive statistics showed no difference between the groups in crowding pre-treatment. Comparison of the difference in the rate of tooth alignment (LII scores) changes during treatment for the two bracket groups are shown in Table 2. There was a marginally statistically significant difference in the rate of tooth movement at T_1-T_2 between CLB and SLB (P < 0.05; Table 2).

Comparison of the difference in overall tooth alignment for the LII score between T_0 and T_4 showed faster changes for the CLB compared with SLB over the 4 month alignment and levelling phase. The average percentage alleviation of crowding was higher with CLB (98 per cent) compared with in SLB (67 per cent; Table 3).

Discussion

The results of this study showed that CLBs aligned teeth at a statistically faster rate than SLBs but only during T_1 – T_2 . There was no statistically significant difference between the CLB and SLB during T_2 – T_3 and T_3 – T_4 . This finding is in accordance with previous investigations that compared CLB and SmartClip brackets (Miles, 2005) and Damon 2 SLBs (Barreiro *et al.*, 2005; Miles *et al.*, 2006).

In an *in vivo* study, Miles (2005) compared the effectiveness of SmartClip brackets and Victory conventional twin bracket for initial alignment of the mandibular arch. Fifty-eight patients were recruited and alternately assigned to either one bracket group. LII was used to determine the differences in alignment and measurements were taken before treatment, 10 weeks after initial archwire placement, and then at 20 weeks. A 0.014 inch Damon Cu–NiTi was used as the initial wire and was later changed to 0.016×0.025 inch Damon Cu–NiTi. The author found that at the end of the 20 weeks period, the SmartClip bracket was no more effective in reducing irregularity than a conventional twin bracket ligated with elastomeric modules or stainless steel ligatures with both wire tested.

In the study of Miles *et al.* (2006), 60 patients were recruited in this split-mouth *in vivo* study. One side of the lower arch was bonded with 0.022 inch slot Damon 2 SLBs and the other side with 0.022 inch slot Victory CLBs.

 Table 1
 Distribution of patient gender, malocclusion, age, and pre-treatment Little's irregularity index (LII).

Type of bracket	Male	Female	Class I	Class II division 1	Mean age	Mean pre- treatment LLI
Mini	5	10	7	8	19.5 ± 3.9	12.9 ± 4.5
Damon 3	3	11	6	8	21.9 ± 3.6	12.4 ± 4.4

Table 2 Comparison between the Mini Diamond conventional ligating bracket and the DamonTM 3 self-ligating bracket groups in the Little irregularity index scores at the four treatment intervals: T_0 = pre-treatment and at the first (T1), second (T2), third (T3), and fourth (T4) reviews using the Mann-Whitney *U*-test. IQR, interquartile range.

Brackets types	Mini Diamond (n = 15; F = 10, M = 5)	Damon TM 3 (n = 14; F = 11, M = 3)	Z statistic	P value
$T_0-T_1 \text{ median (IQR)} T_1-T_2 \text{ median (IQR)} T_2-T_3 \text{ median (IQR)} T_3-T_4 \text{ median (IQR)}$	4.95 (2.58)	1.94 (3.07)	-1.724	0.085
	5.35 (2.27)	2.13 (3.01)	-1.964	*
	1.57 (1.22)	0.94 (1.31)	-0.982	0.326
	1.14 (2.39)	0.99 (0.65)	-0.262	0.793

*P < 0.05.

Table 3 Little's irregularity index scores between before alignment (T_0) , after alignment (T_4) , and percentage of improvement for Mini Diamond conventional ligating and DamonTM 3 self-ligating brackets during the levelling and aligning stage.

Type of bracket	n	Mean T ₀ (mm)	Mean T ₄ (mm)	Mean T ₀ -T ₄ (mm)	Mean percentage improvement
Mini Diamond	15	12.9 ± 4.5	0.3 ± 0.9	12.6 ± 4.7	97.6±8.2
Damon 3	14	12.4 ± 4.4	3.8 ± 1.4	8.6 ± 4.3	67.1±13.4

Similarly, the LII was scored for both sides at baseline, at 10 weeks, and at the 20 weeks archwire change. The same archwires as used by Miles (2005) study utilized. They found that at both archwire changes, the Victory CLBs had a lower LII score than the Damon 2 bracket (0.2 mm). Although this finding was not clinically significant, it showed that the Damon 2 SLB were no better than CLB during the initial alignment stage of orthodontic treatment.

Pandis *et al.* (2007) investigated *in vitro* the duration of mandibular crowding alleviation with SLB (Damon 2) compared with conventional appliances (Microarch) and the accompanying dental effects. They recruited 54 patients with no spaces in the mandibular permanent dentition and with a LII score greater than 2. All patients were treated non-extraction and the time for alignment was estimated in

days. Lateral cephalometric radiographs were used to assess mandibular incisor position pre- and post-alignment stages. Measurements of the intercanine and intermolar widths were also performed on dental casts to determine the changes associated with correction. They observed that, in general, there was no difference in the time needed to correct mandibular crowding either with Damon 2 or with conventional brackets (Microarch) during the initial aligning and levelling stage. However, the Damon 2 brackets aligned the teeth 2.7 times faster than the other bracket type in a moderately crowded (irregularity index less than 5) mandibular arch. For greater crowding with a LII score of more than 5, they found that for every irregularity index unit, treatment was prolonged by an additional 20 per cent regardless of bracket type. In addition, they found a statistically greater intermolar width increase in the Damon 2 group. Proclination of the incisors was observed but there was no difference for this parameter between either bracket type. In that study, crowding alleviation showed a higher percentage with CLB (98 per cent) compared with SLB (67 per cent).

Although Miles et al. (2006) found that there was no difference in bracket efficiency between SLB and CLB during the initial aligning and levelling stage, the result in the present study at T_2 can be explained by the fact that better archwire engagement was possible with CLB. Although no figure-of-eight configuration was used during treatment, full archwire engagement with maximum contact of the archwire with the bracket slot were easily achieved when placing the elastomeric modules on the bracket wings as compared with SLB. Movement of the teeth was facilitated by the friction between the archwire-slot-module interfaces so that the teeth could be aligned by the preformed NiTi archwires at a faster rate.

The teeth of a number of patients were rotated to a moderate degree. Despite the fact that orthodontic brackets were bonded to these teeth, elastomeric modules were not fully engaged at both the mesial and the distal wings. The modules were placed sufficiently to hold the archwire to the bracket to avoid dislodgement of the bracket from the tooth surface. At T_1 and T_2 , the rotated teeth were slowly aligned and subsequently full ligation of the modules to the bracket wings was carried resulting in full engagement of the archwire within the bracket slot, which in turn facilitated tooth movement.

Despite the fact that the Damon bracket was successfully bonded on the rotated tooth surfaces, closure of the metal slot could not be carried out due to excessive bending of the archwire at T_1 . This resulted in no engagement of the archwire within the bracket slot. In this case, a 0.010 inch stainless steel ligature archwire was used to secure the NiTi archwire to the bracket. Failure of archwire engagement within the slot significantly affected the rate of tooth movement in terms of relieving crowded arches. However, as the rotated teeth slowly aligned as treatment progressed, the aligning archwire was able to be fully inserted within the bracket slot during the subsequent visits.

For the purpose of comparison in alignment and levelling, a 0.014 inch NiTi archwire was used throughout the aligning phase despite the larger bracket slot dimension of the passive DamonTM 3 SLB used in the present study. Miles *et al.* (2006) postulated that the presence of 'play' between the smaller archwire dimension and the slot when the 0.014 inch archwire was fitted within the 0.028 inch slot depth Damon 2 bracket (0.0275 + 0.0010-in/-0.0000 in slot tolerance, data from Ormco) would allow 8.5 degree of rotational play compared with a theoretically fully engaged archwire in conventional twin bracket. Scott *et al.* (2008) found no difference in initial alignment between the Damon 3 and conventional brackets with respect to discomfort.

The limitations of this study are with regard to the system recommended by the manufacturer of the SLB. The study protocols were relatively strict to avoid bias to either type of brackets. Therefore, the recommended system for DamonTM 3 SLB could not be applied. Furthermore, measurement of crowding using LII only measured the contact point displacement of the six anterior teeth, which did not represent true tooth movement. Arch length was not measured prior to or after alignment to detect whether alignment was due to mesial distal movement or proclination of the teeth.

Conclusions

The results of this study indicate that in general, SLB are not superior to CLB in terms of tooth alignment during the aligning and levelling stage, although the alignment of incisor teeth during the first month was at a significantly faster rate. Furthermore, CLB showed 98 per cent of crowding alleviation compared with 67 per cent for SLB after 4 months of alignment and levelling.
