Journal of Clinical Periodontology

# Rheumatoid arthritis and salivary biomarkers of periodontal disease

Mirrielees J, Crofford LJ, Lin Y Kryscio RJ, Dawson DR, Ebersole JL, Miller CS. Rheumatoid arthritis and salivary biomarkers of periodontal disease. J Clin Periodontol 2010; 37: 1068–1074. doi: 10.1111/j.1600-051X.2010.01625.x.

#### Abstract

**Aim:** To test the hypothesis that rheumatoid arthritis (RA) influenced levels of salivary biomarkers of periodontal disease.

**Methods:** Medical assessments, periodontal examinations and pain ratings were obtained from 35 RA, 35 chronic periodontitis and 35 age- and gender-matched healthy controls in a cross-sectional, case–controlled study. Unstimulated whole saliva samples were analysed for interleukin-1 $\beta$  (IL-1 $\beta$ ), matrix metalloproteinase-8 (MMP-8) and tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ) concentrations.

**Results:** The arthritis and healthy groups had significantly less oral disease than the periodontitis group (P < 0.0001), with the arthritis group having significantly more sites bleeding on probing (BOP) than matched controls (P = 0.012). Salivary levels of MMP-8 and IL-1 $\beta$  were significantly elevated in the periodontal disease group (P < 0.002), and IL-1 $\beta$  was the only biomarker with significantly higher levels in the arthritis group compared with controls (P = 0.002). Arthritis patients receiving anti-TNF- $\alpha$  antibody therapy had significantly lower IL-1 $\beta$  and TNF- $\alpha$  levels compared with arthritis patients not on anti-TNF- $\alpha$  therapy (P = 0.016, 0.024) and healthy controls (P < 0.001, P = 0.011), respectively.

**Conclusion:** RA patients have higher levels of periodontal inflammation than healthy controls, i.e., an increased BOP. Systemic inflammation appears to influence levels of select salivary biomarkers of periodontal disease, and anti-TNF- $\alpha$  antibody-based disease-modifying therapy significantly lowers salivary IL-1 $\beta$  and TNF- $\alpha$  levels in RA.

Accepted for publication 24 August 2010

The diagnosis of periodontal disease in dentistry is historically based on the clinical detection of bleeding on probing (BOP), pocket depth (PD), clinical attachment loss (CAL), plaque index (PI) and radiographic evidence of bone

# Conflict of interest and source of funding statement

The authors report no conflicts of interest related to this study.

This study was supported by grants from the National Institute of Health P20 RR020145 and M01-RR02602, Bethesda, Maryland, and the University of Kentucky General Clinical Research Core. loss. The diagnostic utility of these clinical measures results from their ease of use, relative non-invasiveness and reliability. However, the time, cost and professional expertise required to complete these procedures accurately have led the profession to search for additional chair side measures to aid in early diagnosis and monitoring. Previous studies have shown that the constituents present in oral fluids (i.e., gingival crevicular fluid and saliva) can provide important complimentary information diagnostic (Malamud 1992, Fox 1993, Kaufman & Lamster 2000, Kaufman & Lamster 2002, Giannobile et al. 2009), with saliva being appealing for its advantages of being a rapid, non-invasive, readily abundant diagnostic fluid potentially useful for point-of-care analysis for dental professionals and the general public (Malamud et al. 2005, Christodoulides et al. 2007).

Studies have shown that levels of certain salivary biomarkers are elevated in individuals who have periodontal disease (Pederson et al. 1995, Lamster et al. 2003, Christodoulides et al. 2007, Ng et al. 2007, Scannapieco et al. 2007, Frodge et al. 2008, Tobon-Arroyave et al. 2008). In particular, biomarkers associated with distinct biological phases of periodontal disease (i.e., inflammation,

collagen degradation and bone remodelling) have been suggested to be useful for early recognition of patients with periodontitis (Miller et al. 2006). Within this context, several biomarkers including interleukin (IL)-1 $\beta$ , C-reactive protein, matrix metalloproteinase (MMP)-8 and -9, tissue inhibitor of matrix metalloproteinase-1, tumour necrosis factor (TNF)- $\alpha$ , receptor activator of nuclear factor-kB ligand and pyridinoline cross-linked carboxyterminal telopeptide of type I collagen have been investigated (Bertolini et al. 1986. Assuma et al. 1998, Azuma et al. 2000, Gorska & Nedzi-Gora 2006, Miller et al. 2006, Gursoy et al. 2010, Miller et al. 2010).

A concern with the clinical use of salivary biomarkers as an adjunct to identify periodontal disease is the possibility that systemic inflammation resulting from various chronic inflammatory diseases may confound the utility of the biomarkers. This concern arises because whole saliva contains serum-derived components, and mediators of inflammation, collagen breakdown or bone remodelling that are elevated in serum of persons with conditions such as rheumatoid arthritis (RA) and could appear in saliva (Ben-Aryeh et al. 1978, Miller et al. 2010). RA is a chronic inflammatory disorder that exhibits soft and hard tissue destruction similar to that of periodontal disease (Snyderman & McCarty 1982). In as much as certain inflammatory mediators such as IL-1 $\beta$ , MMP-8 and TNF- $\alpha$  that have been shown to be elevated in the inflamed joints and serum of patients with RA (Tchetverikov et al. 2004, Eklund et al. 2007, Marti et al. 2009), it is possible that persons with RA or other inflammatory arthritides could have increased levels of these potential biomarkers in their saliva. Of great interest also, periodontal disease has a positive association with RA (de Pablo et al. 2008, Pischon et al. 2008, de Pablo et al. 2009), and it has been proposed that chronic Porphyromonas gingivalis infection of the periodontal sulcus may be a source of citrullinated peptides that could serve as antigens that trigger RA (Wegner et al. 2010). For these reasons, it may be useful to identify periodontal disease in patients with RA or at risk for RA. In the absence of published studies on this topic, this investigation sought to test the hypothesis that RA influences levels of salivary biomarkers of periodontal disease.

# Material and Methods

One hundred and five patients were enrolled in this cross-sectional casecontrolled clinical study performed at the University of Kentucky. Thirty-five patients with the diagnosis of active RA for at least 3 years, as defined by the American College of Rheumatology criteria (Arnett et al. 1988), and under the care of a board-certified rheumatologist at the University, 35 patients with chronic adult periodontitis based on the criteria defined by the American Academy of Periodontology (Armitage 1999, Armitage 2004) and 35 healthy controls were enrolled. The groups were matched by age and gender.

Inclusion criteria included  $\geq 18$  years of age who were in good general health (excluding the case definition) and had  $\geq$  18 erupted teeth. Subjects in the periodontitis group had  $\geq 30\%$  of sites with BOP,  $\geq 20\%$  of sites with PD $\geq 4$  mm,  $\geq 10\%$  of sites with interproximal CAL≥2mm and evidence of alveolar crestal bone loss  $\ge 2 \text{ mm}$  at  $\ge 30\%$  of sites visible in posterior vertical bitewing films. The healthy controls had <10%sites with BOP, <2% of sites with  $PD \ge 5 \text{ mm}$ , no sites with  $PD \ge 6 \text{ mm}$ , <1% of sites with clinical AL $\ge 2$  mm and no radiographic bone loss evident in posterior vertical bitewings films. Exclusion criteria were a history of alcoholism; liver, kidney, or salivary gland dysfunction; inflammatory bowel disease; granulomatous diseases; or were undergoing or had undergone organ transplant or cancer therapy. Pregnancy, use of antibiotics or immunosuppressant medication (non-RA groups only) within the last 6 months, need for antibiotics for infective endocarditis prophylaxis during dental procedures, symptoms of acute illness (i.e., fever, sore throat, body aches and diarrhoea), orthodontic appliances or the presence of an oral mucosal inflammatory condition (e.g., aphthous, lichen planus, leukoplakia and oral cancer) also were exclusion criteria. The use disease-modifying anti-rheumatic of drugs (DMARDs) was permitted in the RA group. The study was performed at the University of Kentucky between August 2005 and October 2007 and was approved by the University Institutional Review Board. All subjects understood the study, provided written informed consent and received incentives (i.e., monetary compensation and a clinical examination) as part of the study protocol.

# **Clinical evaluation**

Complete medical and dental histories were obtained from the patient's records and confirmed by interview. Clinical periodontal indices including PI, PD, BOP and CAL were recorded for each subject by one calibrated examiner [periodontist (D. R. D.)] after the collection of saliva. Measures for PI. PD and BOP were recorded from six locations per tooth (mesial-buccal, mid-buccal, distal-buccal, mesial-lingual, mid-lingual and distal-lingual) using a PUNC 15 probe (Hu-Friedy, Chicago, IL, USA). CALs were obtained by measuring interproximal sites only, and gingival recession was measured on the facial and lingual surfaces only. The level of overall body pain for each RA patient at the time of saliva collection was recorded using a 10 cm line visual analogue scale as reported previously (Danhauer et al. 2002).

#### Saliva collection

Unstimulated whole expectorated saliva was collected from each subject between 9 and 11 a.m. according to a modification in the method described by Navazesh (1993). Subjects rinsed their mouth with tap water, then expectorated whole saliva into sterile tubes while seated in an upright position. Collected samples were placed immediately on ice and aliquoted before freezing at  $-80^{\circ}$ C. Samples were thawed and analysed within 6 months of collection.

#### **Biomarker analysis**

Concentrations of salivary IL-1 $\beta$  and TNF- $\alpha$  were determined in duplicate using Luminex human cytokine/chemokine multiplex kits (Millipore, St. Charles, MO, USA) and salivary levels of MMP-8 were determined in duplicate for each subject using human quantikine MMP-8 enzyme-linked immunosorbent assay kits (R&D Systems, Minneapolis, MN, USA) according to the manufacturer's directions by technologists in the University of Kentucky General Clinical Research Center Core laboratory. Standards were included on all runs and all results are reported within the linearity of the assays.

#### Statistical analysis

Demographic variables were compared among RA, healthy and periodontitis

groups using a chi square test or Fisher's exact test for categorical responses and analysis of variance (ANOVA) for interval level responses. Mean periodontal indices and concentrations of the salivary analytes were compared between the groups using analysis of covariance with adjustments for race, tobacco use and alcohol use. To determine the sensitivity of the results to large values of the biomarkers, a re-analysis using logtransformed responses was conducted. Because these usually produced similar results, this re-analysis is not reported here with the exception of TNF- $\alpha$  where the Kolmogrov-Smirnov test for normality indicated a log transformation was warranted. The periodontal indices were regressed on the biomarkers with possible differences in intercepts and slopes due to group membership. A reanalysis of the comparison of mean periodontal indices and the regression models, which account for differences among the groups on alcohol use, tobacco use and race were conducted but because the results did not change. only the simpler analyses are reported here. All analyses were performed using the PC SAS 9.1 (SAS Institute Inc., Cary, NC, USA) with statistical significance determined at the 0.05 level.

# Results

Thirty-five RA patients ranging in age from 22 to 64 years were enrolled and matched with 35 healthy controls and 35 periodontitis patients (Table 1). Subjects were predominantly females and Caucasians. There were more smokers in the RA and periodontitis groups, and alcohol use was significantly more common in the RA and healthy groups than the periodontitis group. The mean number of teeth for the three groups was similar, as was the  $%CAL \ge 2 \text{ mm}$  between the healthy and RA groups. A higher PI, %PD sites  $\geq 4 \text{ mm}$  and %PD sites  $\geq$  5 mm, was observed in the RA group compared with the controls (P > 0.05), additionally the %BOP was significantly higher in the RA group than the controls (P = 0.012). The periodontal disease group had significantly higher values for all clinical periodontal measures compared with the RA and healthy groups (P < 0.0001).

Individuals in the RA group were under routine care of a rheumatologist. The mean number of DMARDs was 1.2  $(\pm 0.8)$  per patient and the group mean Table 1. Comparison of demographics and clinical characteristics between study groups

\*Determined by Fisher's exact test.

\*\*Determined by ANOVA and applies to comparisons of periodontitis versus RA or healthy.

\*\*\*Determined by ANCOVA and applies to comparisons of RA *versus* healthy.

VAS pain score was  $3.6 \text{ cm} (\pm 2.1 \text{ cm})$ . Eighteen RA subjects took monoclonal anti-TNF medication (Mab) with or without methotrexate, nine took methotrexate, three took leflunomide with methotrexate, hydroxychloroquine or Mab and eight took no DMARDs. Four patients were on prednisone and 18 of the RA patients also took analgesic/non-steroidal anti-inflammatory drugs daily.

Salivary levels of MMP-8, IL-1 $\beta$  and TNF- $\alpha$  in the three groups are represented as box plots in Fig. 1. When adjusted for race and use of alcohol and tobacco, mean levels of IL-1 $\beta$ were significantly elevated (4.18 to 5.2 times) in the RA and periodontitis groups compared with the healthy controls (P < 0.002 and < 0.04, respectively). Subgrouping the RA patients into those on Mab-based therapy and those receiving other/no DMARDs demonstrated that this difference was related to elevated salivary IL-1 $\beta$  levels from the RA patients not receiving Mab (223.24 pg/ml) versus those on therapy (73.35 pg/ml; P = 0.016) and healthy subjects (33.11 pg/ml, P<0.001).

Adjusted mean MMP-8 levels were significantly elevated ( $\geq 3.6$  times) in the periodontitis group compared with the control and RA groups (P < 0.0001), irrespective of the subgrouping of the RA patients. TNF- $\alpha$  levels were higher in the RA group than the healthy and periodontal disease groups although the difference was not significant (P = 0.20). Subgrouping the RA patients by Mab therapy showed that raw responses of

TNF- $\alpha$  did not differ significantly among the groups. However, the frequency of outlier TNF- $\alpha$  levels ( $\geq$ 95th percentile) occurred more frequently in the RA subjects (22.9%) than the periodontal disease subjects (11.4%) and healthy controls (8.6%); thus, the results were re-analysed based on log-transformed biomarker levels. Following this analysis, TNF- $\alpha$  levels in the RA group not treated with Mab were significantly higher than RA treated with Mab (P = 0.024) and healthy subjects (P = 0.011). No periodontal clinical differences were observed between the subgroups of RA patients (data not shown).

We next investigated whether the RA group displayed unique relationships between salivary biomarker levels and any of the clinical parameters of periodontal disease compared with the periodontal disease and healthy groups. As expected, levels of MMP-8 in the periodontitis group significantly correlated with %PD sites  $\geq 4 \text{ mm}$ , %PD sites  $\geq 5 \text{ mm}$  and %BOP (P = 0.04, 0.01,0.04, respectively, Fig. 2). However, the relationship between MMP-8 levels and periodontal measures was only observed with %PD sites  $\geq 5 \text{ mm}$  in the Mab arthritis group (Pearson's r = 0.63, P = 0.02), and not in the healthy group, RA group or non-Mab arthritis group, and MMP-8 levels in the Mab arthritis group were much lower than in the periodontal disease group. IL-1 $\beta$  levels showed a positive correlation with %PD sites  $\geq 4$  and  $\geq$  5 mm in the periodontitis group (r = 0.29 and 0.27, respectively); how-

*Fig. 1.* Box plots of salivary biomarker levels (A) IL-1 $\beta$ , (B) TNF- $\alpha$  and (C) MMP-8 in the three study groups. Horizontal lines, the 25th, 50th and 75th percentiles; +, the mean; **\***, outliers; RA, rheumatoid arthritis; Mab\_Y, RA patients on monoclonal anti-TNF- $\alpha$  antibody therapy; Mab\_N, RA patients not receiving monoclonal anti-TNF- $\alpha$  antibody therapy; P, periodontal disease group; IL-1 $\beta$ , interleukin-1 $\beta$ ; TNF- $\alpha$ , tumour necrosis factor- $\alpha$ ; MMP-8, matrix metalloproteinase-8.

ever, this relationship was not significant and did not occur in the healthy, RA or RA subgroups. TNF- $\alpha$  levels significantly correlated with %CAL $\ge$ 2 mm (r = 0.38, P = 0.026) in the healthy group only. Other factors (i.e., the number of teeth, level of pain, DMARD use and demographics) did not correlate with the levels of salivary biomarkers or significantly influence the level of salivary biomarker per group (data not shown).

# Discussion

This study investigated the influence of RA on salivary levels of three biomarkers (IL-1 $\beta$ , MMP-8 and TNF- $\alpha$ ) associated with periodontitis. The effects were examined using three study groups (healthy, RA and chronic adult periodontitis) with the premise that if RA was influential, then the salivary biomarker levels would be altered with respect to levels observed in the periodontitis or healthy groups. We found that salivary levels of IL-1 $\beta$  were significantly elevated in the overall RA group compared with a control group with similar levels of periodontal disease, whereas MMP-8 and TNF- $\alpha$  were not. As expected, we demonstrated elevations in the concentrations of these salivary biomarkers in patients with periodontal disease compared with healthy controls. However, salivary levels of IL-1 $\beta$  and TNF- $\alpha$  did not reliably differ between the periodontal disease group and RA group who had less severe periodontal disease. When the RA subjects were stratified into subgroups based upon the presence or absence of anti-TNF-α Mab therapy, we showed that salivary IL-1 $\beta$  and TNF- $\alpha$  biomarker levels were strongly influenced by this treatment, whereas MMP-8 levels were not.

This study is the first to examine the influence of a systemic inflammatory condition and its treatment on salivary biomarkers of periodontal disease. IL- $1\beta$ , MMP-8 and TNF- $\alpha$  were investigated because these salivary biomarkers have associations with biological aspects of periodontitis, and have been shown to be significantly elevated in periodontitis subjects compared with healthy controls (Miller et al. 2006, Christodoulides et al. 2007, Ng et al. 2007; Scannapieco et al. 2007, Frodge et al. 2008, Tobon-Arroyave et al. 2008, Gursoy et al. 2010). Specifically related to the findings in this report is the current emphasis and emerging potential for targeted salivary biomarkers to serve in point-of-care diagnostic monitoring of periodontal health and as an adjunct in the management of periodontal disease (Ramseier et al. 2009, Miller et al. 2010). These markers were studied in the context of RA. because this chronic inflammatory disorder has a positive association with periodontitis (Kasser et al. 1997, Mercado et al. 2000, Mercado et al. 2001, Havemose-Poulsen et al. 2006, Pischon et al. 2008, Biyikoglu et al. 2009) and elevated levels of

*Fig.* 2. Scatter gram and least squares line between (A) MMP-8 level and %BOP and (B) MMP-8 level and %PD sites  $\geq 5$  mm by group. In (A), the slopes for the Mab\_Y and P group were significant (r = 0.63, P = 0.02; r = 0.42, P = 0.01, respectively), and in (B) only the slope for the P group was significant (r = 0.36, P = 0.04). Group H, healthy; Mab\_Y, RA on anti-TNF- $\alpha$  therapy; Mab\_N, RA not on anti-TNF- $\alpha$  therapy; P, periodontitis; MMP-8, matrix metalloproteinase-8.

these inflammatory mediators occur in the serum of RA patients (Tchetverikov et al. 2004, Eklund et al. 2007, Marti et al. 2009). Moreover, the potential for inflammatory mediators to appear in saliva during autoimmune conditions has been demonstrated (Ben-Aryeh et al. 1978, Tishler et al. 1999).

MMP-8, a highly sensitive measure of periodontal disease (Sorsa et al. 1994) proved to be a significant predictor of %PD sites  $\geq 5 \text{ mm}$ , %PD sites  $\geq 4 \text{ mm}$ and %BOP in the 35 periodontitis patients studied here as well as in other studies (Miller et al. 2006, Herr et al. 2007, Miller et al. 2010). Salivary levels of MMP-8 were unaffected in the RA group, irrespective of DMARD and anti-TNF- $\alpha$  Mab therapy. This finding is consistent with MMP levels in the gingival crevicular fluid of patients with RA and gingivitis or periodontitis being similar to their systemically healthy counterparts (Bivikoglu et al. 2009).

Salivary IL-1 $\beta$  levels were significantly elevated in the periodontitis and RA group compared with the controls.

Although these elevated levels were consistent with the RA group having a significantly higher %BOP score, and higher PI, %PD≥4 and 5mm, and %CAL scores than the healthy controls, this does not fully explain the elevated levels. The RA group had clinical measures less severe than the periodontitis group despite the salivary IL-1 $\beta$  levels being higher in the RA group, suggesting that salivary IL-1 $\beta$  was elevated due to systemic inflammation. By stratifying the RA patients into subgroups based upon treatment with anti-TNF- $\alpha$  Mab therapy, it was revealed that the RA group treated with Mab had significantly lower salivary IL-1 $\beta$  levels. Similarly, in the log-transformed data analysis, salivary levels of TNF- $\alpha$  in the RA group treated with Mab were significantly lower than RA treated with Mab and healthy subjects. In as much as, there were no periodontal clinical differences between the RA subgroups (data not shown), these findings suggest that anti-TNF Mab therapy can influence salivary biomarkers of periodontal disease. Also, the fact that treatment with a Mab-reduced salivary IL-1 $\beta$  and TNF- $\alpha$  could be a reflection of reduced RA disease activity and/or a specific effect on the inflammatory components of periodontal disease.

The findings presented here are to be viewed within the context of the limitations of its cross-sectional study design and the fact that the majority of the RA subjects were females, Caucasians and medically well controlled. Seventyseven percent of the RA subjects took at least one DMARD, more than half took analgesics/non-steroidal antiinflammatory drugs daily and the majority had low VASs. Because these therapies could have attenuated circulating serum and salivary biomarker levels, as has been shown in a study of hydroxychloroquine, an anti-inflammatory drug for primary Sjögren's syndrome (Tishler et al. 1999), we subgrouped the RA patients by VAS, Mab and DMARD use. In these analyses, only anti-TNF-a Mab use proved to demonstrate subgroup differences.

These studies are of particular relevance as a relationship between periodontal disease and other chronic inflammatory diseases, including RA, are being suggested as phenotypic manifestations of a hyperinflammatory genotype in a subset of the population. Accumulating evidence suggests that periodontitis and RA are inter-related and possibly interdependent with respect to the elevated levels of serum pro-inflammatory molecules that likely contribute to the milieu of the gingival crevicular fluid and thus the saliva. Thus, the potential altered abilities of RA patients to perform effective oral hygiene could result in an increased BOP that exacerbates the risk for an enhanced tissue destruction in periodontitis. Moreover, interesting observations regarding the complexity of the oral and systemic challenge provide unique mechanisms by which dysregulation of host responses could occur. For example, P. gingivalis has the ability to generate citrullinated proteins that can serve as antigens that can drive an autoimmune response (Wegner et al. 2010). Finally, the observation that anti-TNF-a Mab therapy was associated with lower levels of periodontal disease biomarkers in patients with RA further supports some common hyperinflammatory mechanisms in these diseases. This type of finding emphasizes opportunities to evaluate biological therapies for

periodontitis that would specifically target selected pro-inflammatory mediators for control in the local oral environment (Assuma et al. 1998).

# Conclusions

This study provides evidence that salivary IL-1 $\beta$ . MMP-8 and TNF- $\alpha$  levels are clearly influenced by the local periodontal environment, and selectively influenced by a systemic inflammatory condition such as RA. The findings provide further support for the clinical utility of salivary biomarkers in assessing periodontal disease in otherwise healthy adults, although additional studies are required to more clearly delineate the impact of systemic inflammatory disease(s) and co-morbidities on profiles of salivary biomarkers that could be used in monitoring health and/or defining oral disease.
