Mandibular necrosis in beagle dogs treated with bisphosphonates

Structured Abstract

Authors - Burr DB, Allen MR

Objectives – To test the effect of bisphosphonate (BP) treatment for up to 3 years on bone necrosis and osteocyte death in the mandible using a canine model.

Materials and Methods – Dogs were treated with clinical doses of oral alendronate (ALN, 0.2 or 1.0 mg/kg/day) for 1 or 3 years. In a separate study, dogs were treated with i.v. zoledronate (ZOL) at 0.06 mg/kg/day for 6 months. *En bloc* staining was used to identify necrotic areas in the mandible; viable osteocytes were identified using lactate dehydrogenase.

Results – None of the treatments was associated with exposed bone, but 17–25% of dogs treated for 1 year and 25–33% of dogs treated for 3 years with ALN showed pockets of dead bone. Necrotic areas had no viable osteocytes and were void of patent canaliculi. No control animals demonstrated necrotic bone. ZOL treatment for 6 months was associated with osteocyte death greater than that seen in animals treated with ALN or saline. It is not clear whether osteocyte death occurs because of direct toxic effects of BPs, or because suppressed remodelling fails to renew areas that naturally undergo cell death. Necrotic areas are also associated with bone other than the mandible, e.g. the rib, which normally undergo high rates of remodelling.

Conclusions – Reduced remodelling rate using BPs may contribute to the pathogenesis of bone matrix necrosis. The development of an animal model that mimics important aspects of BP-related osteonecrosis of the jaw is important to understanding the pathogenesis of osteonecrosis.

Key words: bisphosphonates; mandible; osteocytes; osteonecrosis

Introduction

Osteonecrosis of the jaw (ONJ) was first identified as a serious potential health-related problem only 5 years ago (1–3). Since 2005, the number of publications describing the condition, its possible pathogenesis, prevention, treatment and the role that bisphosphonates (BP) may or may not play in the initiation or progression of the condition have multiplied by more than threefold to reach approximately 160 annually (Fig. 1). Most of

Fig. 1. The number of citations in PubMed between 2003, when bisphosphonate-related osteonecrosis was first identified, and June of 2008. Following a search using the terms 'Bisphosphonates and osteonecrosis', citations specific to the jaw (e.g. excluding osteonecrosis of the femoral head) were identified.

these reports are retrospective studies of the epidemiology and risk factors associated with the condition (e.g. see reference 4 for one of the better reports). These reports, while useful, will never be able address the root causes or pathogenesis of the condition, nor allow us to study any means by which the condition can be either prevented or treated.

In part for this reason, the American Society for Bone and Mineral Research (ASBMR) Task Force on Bisphosphonate-Associated Osteonecrosis of the Jaw (BRONJ) recommended as necessary and essential 'the development of an appropriate animal model' [emphasis ours] to determine the best management approach to those with ONJ. They state, 'such an animal model, once developed would hopefully provide the rational/ethical basis on which human randomized clinical trial investigations could occur'. BRONJ was defined by the ASBMR Task Force as 'an area of exposed bone in the maxillofacial region that does not heal within 8 weeks after identification by a healthcare provider, in a patient who was receiving or had been exposed to a BP and did not have radiation therapy to the craniofacial region (5). Thus, an animal model for BRONJ would have to be one treated with a BP which developed exposed bone, perhaps in response to an infection or a dental procedure/trauma, which persisted for at least a period equivalent to the period of time required for normal healing in that animal species. In a dog, this would be equivalent to 4-6 weeks. No such model currently exists, and the issue of what an appropriate model might depend in part on the role that bone remodelling plays in the pathogenesis of BRONJ.

We have been using oral BPs in a non-ovariectomized canine model to investigate the effect that BPs have on the mechanical and material properties of the bone tissue. As a serendipitous part of these studies, we collected mandibles from dogs that were treated with oral doses of alendronate (ALN; Fosamax, Merck & Co., Inc., West Point, PA, USA) at doses used for the clinical treatment of osteoporosis (on a mg/kg basis), or at $5\times$ that dose. Treatment with ALN occurred over 1, 2 or 3 years. The experimental design of this study, and data on bone properties not related to ONJ have been reported in several publications (6–11). Data on the changes to the mandible were reported earlier in 2008 as well (12).

En bloc basic fuchsin staining is a technique developed to identify the accumulation of microdamage in bone and to distinguish it from artifact caused by histological processing and sectioning (13-15). This process was also used by Frost (13) and Enlow (16) nearly 50 years ago to identify areas of bone (primarily rib) that were necrotic. Basic fuchsin works by passively diffusing into all voids in the bone tissue matrix (blood vessels, lacunae, canaliculi and microcracks). Areas that do not stain lack a patent canalicular network that would allow diffusion of the stain into the empty spaces. Therefore, large regions void of stain can be easily identified using either standard transmission or confocal microscopy. Areas of necrotic bone can also be assessed using enzyme histochemistry for viable osteocytes. Our laboratory utilizes lactate dehydrogenase (LDH) to identify necrotic regions. Living, viable osteocytes produce LDH, and will stain, whereas LDHpositive osteocytes cannot be detected in areas of nonviable bone.

Basic fuchsin staining was applied to cross-sections taken from various locations through the mandibles of dogs that had been treated for 1 or 3 years with ALN or vehicle (n = 12/dose or group). Sections were made through the level of the 2nd premolars, between the 3rd and 4th premolars and through the 1st and 2nd molars (Fig. 2). These sections were subsequently stained *en bloc* with basic fuchsin, and viewed with a standard transmission microscope and with a confocal microscope. Areas devoid of stain that were at least 500 μ m² in area were considered necrotic. Based on this, we found 25% (n = 3) of the animals treated for 3 years

Fig. 2. Experimental design for the initial experiments treating dogs for 1 or 3 years with two different doses of oral alendronate. The lower dose is the dose used to treat post-menopausal women with osteoporosis; the higher dose is used to treat Paget's disease. Dogs were 1- to 2-years old at the initiation of treatment. Calcein labelling was initiated 3 weeks prior to sacrifice. Sections were taken at four locations through the mandible.

with osteoporosis doses of ALN, and 33% (n = 4) of those treated with a higher dose for 3 years, had regions of necrotic bone (Fig. 3). Three of the animals (n = 2 treated with the lower dose and n = 1 treated with the higher dose) had two separate regions of necrosis within the same tissue section. None of the 12

animals treated with saline vehicle for 3 years demonstrated necrotic regions of bone. Those dogs treated for only 1 year with the lower dose of ALN also demonstrated a 25% incidence of mandibular necrosis at the osteoporosis dose, and 17% (n = 2) incidence at the higher dose (Table 1). Again, no animals in the vehicle control group demonstrated any regions of necrotic bone in the mandible. Necrotic lesions in BP-treated animals were primarily restricted to the alveolar bone region, an area of rapid bone turnover under normal conditions, although two animals treated with the higher dose of ALN for 3 years had necrotic areas in the corpus or at the base of the mandible, where remodelling occurs at lower rates.

Table 1. Mandible necrosis summary

Treatment	Dose (mg/kg/day)	Animals	Sites per animal	Animals w/necrosis
1 year treatment

3 year treatment				
Vehicle		12	4	0
Alendronate	0.2	12	4	3 (25%)
	1.0	12	4	4 (33%)

Fig. 3. Photomicrographs of mandible bone matrix necrosis in beagle dogs treated with bisphosphonate. Following 1 or 3 years of oral alendronate treatment, mandibles were stained *en bloc* with basic fucshin which allows identification of necrotic bone matrix due to its lack of stain uptake compared to viable regions of bone. Images are from three different animals treated with oral alendronate for 1 or 3 years.

It is important to stress that treatment with oral BPs, even at high doses for 3 years in these dogs, did not create BRONJ, as defined above, in any of the dogs. Nevertheless, treatment was associated with necrotic bone in that osteocytes in significant pockets of bone tissue were dead. We suggest that this may be an indication of pre-ONJ that does not progress to exposed bone unless there are other precipitating factors (e.g. trauma, infection, compromise of the immune-system or some combination of these well-defined risk factors).

Most instances of BRONJ have involved i.v. administration of zoledronate (ZOL) or pamidronate in patients with cancer who are generally immunesuppressed, and often at doses 10× those used to treat post-menopausal women for osteoporosis. Therefore, our laboratory undertook a short-term study in dogs to compare the effects of oral ALN at the osteoporosis dose (0.2 mg/kg/day) for 3 or 6 months with i.v. ZOL given at the dose used in cancer patients (0.06 mg/kg/month) (unpublished studies). Sections from the mandible were stained using LDH histochemistry and basic fuchsin to assess osteocyte viability and matrix necrosis. In this study, no animals showed evidence of necrosis using basic fuchsin staining. However, using LDH histochemistry there was clear evidence of regions with non-viable osteocytes. The areas of non-viable osteocytes in the alveolar bone were three to 4× greater in animals treated for 6 months with i.v. ZOL compared to animals treated either with ALN or with saline vehicle (Fig. 4). This shows that, even short-term treatment with high doses of ZOL in a healthy dog can lead to significant osteocyte death and necrosis of alveolar bone. Again, however, no areas of exposed bone were visible in the oral cavity of any of these dogs.

The pathophysiology of mandibular necrosis

It is not clear whether osteocyte death subsequent to treatment with BPs in the canine model (or in human BRONJ) occurs through direct toxic effects of BPs on bone cells (17), or whether it occurs through reduced remodelling of regions which normally undergo cell death (Fig. 5). BPs, at doses consistent with those used for osteoporosis, are known to prevent osteocyte apoptosis *in vivo* (18, 19). There is no direct evidence of

Fig. 4. Accumulation of regions with non-viable osteocytes in the mandible is prominent with high dose zoledronate treatment. Following 6 months of treatment with either saline (VEH), oral alendronate (ALN) or i.v. zoledronate (ZOL) mandible tissue was assessed for osteocyte viability using lactate dehydrogenase staining, which results in viable cells staining blue. Using an ordinal scale classification, it can be shown that regions of non-viable osteocytes were more prominent in ZOL-treated animals (panel A). Although both VEH and ALN-treated animals had regions of non-viable osteocytes, there tended to be very few regions and these were small (panel B). Conversely, some of the regions of non-viable osteocytes in ZOL-treated animals were significant in size (panel C).

the *in vivo* effects of BPs on osteocytes at higher doses, although pamidronate and ALN have been shown to inhibit protein prenylation in osteoblasts and to

Fig. 5. Flow chart showing two possible pathways for the accumulation of necrotic bone with non-viable osteocytes. In one situation (left side), bisphosphonates accumulate in the skeletal tissue to levels that become toxic to osteocytes, causing their death and subsequent matrix necrosis. A second pathway (right side) is through reduced remodelling caused by bisphosphonates which would inhibit the repair of osteocytes that die as a consequence of normal physiological processes associated with tissue renewal. Failure to replace the dead osteocytes, would then lead to larger regions of necrosis without viable osteocytes.

negatively affect osteoblast differentiation in vitro (17). ALN (20) and pamidronate (21) have been shown to suppress the activity of osteoblasts in vivo, and Idris et al. (17) recently showed that calvarial osteoblasts are capable of ingesting sufficient amounts of ALN in vivo to inhibit protein prenylation. Therefore, it is possible that high doses of potent BPs delivered over a short period of time, or longer-term administration of less potent BPs, which may nevertheless have a high binding affinity (such as ALN) and remain in the bone for long periods of time (22), may accumulate in the skeleton to levels that become toxic to osteocytes. The alternative hypothesis is that the death of osteocytes and the development of some necrotic bone matrix is normal and it accumulates with BP treatment because remodelling is suppressed. Cell death is a physiological process that occurs in living bone all the time. Usually, dead cells are removed by normal processes of remodelling, but in cases where remodelling is suppressed, these cells may not be removed and may accumulate in pockets of necrotic bone. Which of these two hypotheses is correct - if either is - remains an open question, and one that can probably only be answered using an animal model in which necrosis can be created. In either case, this osteocyte death without replacement inevitably leads to tissue necrosis, which, when combined with a dental extraction or oral

infection, especially in those who are immune-compromised, could progress to frank jaw osteonecrosis.

To begin to understand whether the mechanism underlying the accumulation of necrotic bone matrix is specific to BP, we have assessed mandible tissue from non-ovariectomized beagle dogs that were treated for 1 year with a different anti-remodelling agent, the selective estrogen receptor modulator (SERM) raloxifene (Evista; Eli Lilly and Co., Indianapolis, IN, USA). These animals, treated daily with the clinical dose of oral raloxifene, were part of the same study described above for ALN. To date, we have assessed two different regions of the mandible in these raloxifene-treated animals and have not identified any regions of matrix necrosis (using basic fuchsin staining). Based on analyses of the vertebrae from these raloxifene-treated animals compared to those treated with ALN for 1 year, we know that the turnover suppression is not equivalent (-20% in raloxifene and -70% in ALN compared with vehicle) (6, 23). Therefore, it remains unclear if remodelling suppression to a similar degree as that which occurs with BPs would similarly increase the amount of necrotic bone matrix or whether this effect (accumulation of necrotic bone) is specific to the BPs.

The alveolar process of the mandible normally is subject to a high rate of bone turnover. The cause for this is not known, although it may be related to the large bite forces engendered in this region, or to the need to clear bacterial agents present in the relatively 'dirty' oral environment. Whatever the reason, it has been shown that bone turnover in the alveolar region of the adult canine mandible is $2-4\times$ greater than in the basal portion of the mandible (12, 24), and $15-20\times$ higher than in bones from the appendicular skeleton (24, 25). It is possible that when this high rate of turnover is artificially suppressed with BPs, (Fig. 6) areas which normally undergo cellular necrosis are not remodelled, but accumulate, leading after a period of remodelling suppression to large areas devoid of viable cells. It is possible to test whether a high rate of turnover is associated with osteocyte necrosis by comparing the alveolar process to the basal region of the mandibular corpus, a site of very low turnover (24), and to the rib, a site of high turnover (c. 20%/year, approximately half that in the alveolar process of the mandible, but 10× higher than in other sites in the appendicular skeleton) (26). If suppression of remodelling at sites of normally high turnover is related to the

Fig. 6. Photomicrographs of mandible cross-sections from animals treated for 3 years with vehicle (VEH) or alendronate (ALN). Through administration of fluorochrome labels at the end of the experiment, the level of bone remodelling can be determined using ultraviolet fluorescent microscopy. Based on the number of calcein-labelled osteons it is clear that there is a high level of turnover in VEH animals, particularly in the alveolar portion of the bone. Conversely, far fewer osteons are labelled in the ALN-treated animal, indicative of a reduced remodelling rate.

development of large areas of cellular necrosis, then, we might expect to see necrotic bone in the rib, but not in the basal portion of the mandible, even in those samples in which necrotic bone is found in the alveolus. In fact, this is exactly what we observe. We detected few instances of osteocyte necrosis 500 μ m² or larger at the base of the mandible. However, we found a 20% incidence of necrotic bone in the rib in dogs treated with ALN at the osteoporosis dose, and a 40% incidence with the high dose. Thus, we hypothesize that areas of bone that are normally subject to high rates of turnover, and in which remodelling is artificially suppressed by as much as 85%, are subject to develop necrotic bone. Patches of necrotic bone in non-dental tissues may never represent a serious health problem because they are less subject to trauma in which bone is exposed, are not adjacent to epithelial tissues, and not likely to be exposed to bacterial agents that cause infection or inflammatory processes. It is still not clear, however, whether the regions of necrosis themselves at either site - are caused by a normally high rate of osteocyte death in these regions that simply can no longer be cleared because remodelling is suppressed, or whether the rate of vascular flow in these regions allows more BP to enter these areas, either permitting greater access to bone extracellular fluids around the osteocytes, or permitting greater accumulation in the skeleton, with direct toxic consequences to the osteocytes.

If a high rate of intracortical remodelling is a necessary condition for the pathogenesis of BRONJ, then this reflects on the future development of animal models. Mice and rats may not provide good models for BRONJ because neither of these species, under normal circumstances, has intracortical remodelling in the mandible. Although some have suggested that mandibular remodelling occurs to some degree in C3H/HeJ and C57BL/6J mice, it is not common, nor is it consistent from one mouse to another (27). The marsh rice rat (28)may represent a potential animal model in which mandibular bone can become necrotic. Gotcher and Iee (28) showed that treatment with clodronate at doses between 0.1 and 10.0 mg/kg/day for 6-18 weeks led to necrotic and exposed alveolar bone, especially at the high doses and longest period of exposure. Although rabbits have extensive intracortical remodelling in their long bones, an examination of the adult rabbit mandible suggests that remodelling is not very common in it either. Rabbits injected 3×/week for 8 months with 2.4 mg/kg of ALN or risedronate did not demonstrate any areas of necrotic tissue within the mandible upon sacrifice. Limited osteonal remodelling was found in these rabbit mandibles (Fig. 7).

It seems that the dog, because of its ability to remodel in ways that are similar to humans, may represent the best potential animal model for BRONJ. Demonstration of large areas of necrotic bone in a subpopulation of dogs treated with BPs suggests the possibility that true ONJ could develop under conditions of dental trauma or infection in these animals.

Conclusions

No animal model currently exists that mimics BRONJ. Treatment of dogs for 1–3 years with oral BPs, or for 6 months with i.v. ZOL, is associated with the development of areas of tissue necrosis and dead osteocytes in the mandible and the rib, both sites of high bone turnover rates. It is not clear whether tissue necrosis is related to the toxic effects of BPs at high dose, skeletal accumulation of BPs that are given for prolonged

Fig. 7. Photomicrographs of alveolar bone in a 2-year-old beagle dog (panels A and B) and a 1-year-old rabbit (panels C and D). The difference in osteon density, illustrated using brightfield microscopy of basic fuchsin stained sections (A & C), clearly illustrates the lower rate of secondary osteonal remodelling in the rabbit mandible. This can also be appreciated using polarized light (B and D), which shows the rabbit mandible alveolar process is unremodelled primary bone even in this mature animal. If bisphosphonate-related osteonecrosis of the jaw (BRONJ) is found more often in regions of bone that have high basal remodelling rates, then rabbits are not likely to be a very good animal model for the pathogenesis of BRONJ.

periods of time, or whether the necrosis is simply the result of the natural process of cell death, and that the areas are retained because suppressed remodelling prevents their replacement. These are not questions that are likely to be answered from human clinical studies. The development of an animal model that mimics the most important aspects of BRONJ is vital to our understanding of the pathogenesis of this serious condition.

Clinical relevance

Oral BPs are used to treat osteoporosis, and i.v. BPs at high doses are used to prevent skeletal metastasis in some cancers. BP use has been implicated in the pathogenesis of BRONJ. Attempts to recapitulate BRONJ in an animal model have the potential to improve our understanding of the pathophysiology of BRONJ and provide a new model system to test preventative and therapeutic approaches for this condition.
